I HEREBY CERTIFY THAT THIS CORRESPONDENCE, **CONSISTING OF 17 PAGES OF SPECIFICATION AND 5 PAGES OF DRAWINGS**, IS BEING DEPOSITED WITH THE UNITED STATES POSTAL SERVICE "EXPRESS MAIL POST OFFICE TO ADDRESSEE" SERVICE UNDER 37 CFR 1.10 ON THE DATE INDICATED ABOVE AND IS ADDRESSED TO: BOX PATENT APPLICATION, THE COMMISSIONER OF PATENTS & TRADEMARKS, U.S. PATENT AND TRADEMARK OFFICE, P.O. BOX 2327, ARLINGTON, VA 22202.

BY: _____

Lizzy Perkins

SPECIFICATION

To all whom it may concern:

Be It Known, That I, **Brian E. Corrigan, III**, a citizen of United States of America, residing at **2956 Penstemon Court, Wichita, Kansas 67226**, have invented certain new and useful improvements in "**Method and Apparatus for Protection of Data Utilizing CRC**", of which I declare the following to be a full, clear and exact description:

LSI DOCKET NO. 01-776

BACKGROUND OF THE INVENTION

1. Technical Field:

The present invention is directed generally toward a method and apparatus for protection of data utilizing cyclical redundancy checking.

2. Description of the Related Art:

In a high-performance computer system consisting of multiple processors and mass storage devices, it is of critical importance that all information be stored and retrieved reliably with no errors. It is of equal importance that if errors occur in the storage or retrieval of data, that the errors be detected and reported. Typically, the mass storage of a high-performance computer system consists of a redundant array of independent disks (RAID). Within the RAID mass storage system, data is stored both in semiconductor memory in the RAID controller and on the magnetic media of the RAID disk drives. Though data written to semiconductor memory can be protected using error correction code (ECC) techniques, this will not prevent against inadvertent writes to locations in the memory or reading from incorrect locations. Furthermore, data stored on the disk drives of a RAID system can be stored incorrectly or retrieved incorrectly due to errors in the drives. For example, the drives may have physical problems, data may be stored in the wrong location on the drive, or the data may become corrupted.

The method by which these errors are detected in the system should have minimum impact on the overall system performance. There are several approaches that may be used to protect data from the above-mentioned errors. One method involves the execution of software that checks the integrity of data as it is being stored or retrieved. This method, used to ensure the accuracy of transmitting digital data, is cyclical redundancy checking (CRC). This operation executes concurrently with the transfer of the data. Because this method utilizes a portion of the computing resources for its execution, the overall performance of the system is reduced. This method adds an additional amount of complexity to the software executing in the RAID system.

Another method involves a hardware engine that checks the integrity of data after it has been transferred. Though this method utilizes a small amount of computing resources to

LSI DOCKET NO. 01-776

initialize and start the hardware engine, system performance is reduced due to the time required to initialize the engine and execute the checking algorithm. If a separate hardware engine is used to perform the CRC function after a transfer to or from system memory is completed, then the next system operation or transfer would have to wait until this CRC operation is completed before executing. This reduces system performance.

Therefore, it would be advantageous to provide an improved method and apparatus for protection of data using cyclical redundancy code.

FOR THE

SUMMARY OF THE INVENTION

The present invention provides the addition of a dedicated hardware CRC computation engine to assure the integrity of data transferred between the system memory and storage devices.

The CRC computation engine provides CRC calculation “on-the-fly” for the protection of data transferred to and from the system memory without software overhead. The computation of CRC values and optional checking against previously calculated CRC values is selected through the use of an address-mapping scheme. This CRC protection scheme requires a small amount of initial software overhead to allocate the data, CRC value, and CRC error regions of the system memory.

After the CRC protection scheme is initialized, all CRC operations are transparent to the executing software.

[illegible]

BRIEF DESCRIPTION OF THE DRAWINGS

The novel features believed characteristic of the invention are set forth in the appended
5 claims. The invention itself however, as well as a preferred mode of use, further objects and
advantages thereof, will best be understood by reference to the following detailed description of an
illustrative embodiment when read in conjunction with the accompanying drawings, wherein:

Figure 1 is a block diagram illustrating a storage system in accordance with a preferred
embodiment of the present invention;

10 **Figure 2** is a block diagram depicting an example of logical system memory mapping in
accordance with a preferred embodiment of the present invention;

Figure 3 is a block diagram illustrating data block area and CRC value area in system
memory in accordance with a preferred embodiment of the present invention;

15 **Figure 4** is a flowchart depicting the operation of memory interface logic in accordance
with a preferred embodiment of the present invention; and

20 **Figure 5** is a flowchart illustrating the operation of a CRC hardware engine in accordance
with a preferred embodiment of the present invention.

LSI DOCKET NO. 01-776

DETAILED DESCRIPTION

The description of the preferred embodiment of the present invention has been presented for purposes of illustration and description, but is not limited to be exhaustive or limited to the invention in the form disclosed. Many modifications and variations will be apparent to those of ordinary skill in the art. The embodiment was chosen and described in order to best explain the principles of the invention the practical application to enable others of ordinary skill in the art to understand the invention for various embodiments with various modifications as are suited to the particular use contemplated.

With reference now to the figures and in particular with reference to **Figure 1**, a block diagram illustrating a storage system is shown in accordance with a preferred embodiment of the present invention. Memory interface logic **110** manages the transfer of data from storage devices **122, 130** and host devices **126** via peripheral component interconnect (PCI) interfaces **124, 128, 132** to system memory **140** and from system memory to the storage devices and host devices. Transfers from devices into system memory are writes and transfers from memory to devices are reads.

For example, host devices **126** may write data to system memory **140** for subsequent storage in one of storage devices **122, 130**. As another example, data may be written from one of storage devices **122, 130** to system memory and read from system memory to be transferred to one of host devices **126**. Direct memory access (DMA) controller **148** also transfers blocks of data from memory to storage devices. Furthermore, array parity control **150** takes data in blocks of memory, performs calculations, and creates new data. The array parity control is used in striping data across storage devices.

In accordance with a preferred embodiment of the present invention, CRC hardware engine **160** is provided to assure the integrity of data transferred between the system memory and storage devices accessed through PCI buses. The CRC hardware engine provides CRC calculation on the fly for protection of data transferred to or from the system memory without software overhead.

LSI DOCKET NO. 01-776

The computation of CRC values and optional checking against previously calculated CRC values is selected through the use of a unique PCI address-mapping scheme. The system memory is accessed in one of three modes: normal, generate, and check. In a CRC generate mode access, the PCI address of a memory transfer falls within the range of the CRC Generate base and limit registers 112. For this transfer, a CRC value is calculated and written to CRC value area 144 of system memory by the CRC hardware engine.

In a CRC check mode access, the PCI address of a memory transfer falls within the range of the CRC check base and limit registers 114. For this transfer, a CRC value is calculated and compared against a previously generated CRC value in the CRC value area of the system memory. If the computed value for the data transfer does not compare against the previously computed value, an error in the data is detected. A transfer of error information to CRC error area 146 of system memory by the CRC hardware engine reports the error. In a normal mode access, the PCI address of a memory transfer does not fall within either the CRC generate or CRC check regions.

CRC hardware engine 160 interfaces to memory interface logic 110 via memory monitor bus 172 and CRC hardware memory read/write bus 174. The memory monitor bus provides a status of the current system memory activity to the CRC hardware engine. The starting address, active port identification (ID), data direction, and data for each transaction to or from the system memory is output from the memory interface logic on the memory monitor bus. Additionally, the port indicates to the CRC hardware engine whether the data transfer falls within the CRC Generate region or the CRC Check region. The CRC hardware memory read/write bus is used by the CRC hardware engine to read previously computed CRC values from system memory and to write newly computed CRC values to system memory. CRC hardware memory read/write bus 174 is also used to write CRC error information to system memory.

When a generate memory transfer begins, CRC controller 162 begins calculation of the CRC value. The CRC controller may use, for example, the CRC-32 polynomial to calculate the remainder. As each 128-bit memory word is presented at the memory monitor bus, the calculation is updated. A CRC remainder is calculated on a block-by-block basis. When the

LSI DOCKET NO. 01-776

transfer is completed, the CRC hardware engine writes the calculated CRC values to the system memory via memory bus interface **164**.

When a check memory transfer begins, CRC controller **162** reads previously computed CRC values for the memory block being transferred via memory bus interface **164**. If CRC cache address and flag registers **166** detect that CRC values are already cached, appropriate flags are presented to CRC controller **162** and the values are read from CRC value cache **168** rather than system memory. The CRC remainder calculation then begins with the first word presented at the memory monitor bus and continues until the end of a block is reached. The computed value is compared with the previously computed value to determine if an error is present. If the CRC controller detects an error, the appropriate error information for the block is written to CRC error area **146** of system memory via memory bus interface **164**. The CRC controller may also inform the memory interface logic of the error by, for example, setting an interrupt, generating PCI system errors (PCI SERR), setting status bits, etc.

Turning to **Figure 2**, a block diagram depicting an example of logical system memory mapping is shown in accordance with a preferred embodiment of the present invention. The memory interface logic includes logical memory map **220** that maps an address space to physical system memory **250**. The logical system memory map includes generate mode memory map **222** and check mode memory map **224**. The generate mode memory map address range is defined by generate base and limit registers **212** and the check mode memory map address range is defined by check base and limit registers **214**. As can be seen in **Figure 2**, the generate mode memory map and the check mode memory map both map addresses to CRC protected data area **254** in physical system memory **250**.

A normal mode access may comprise a transfer for any address not between the generate base and limit or between the check base and limit. Alternatively, logical system memory map **220** may include normal mode memory map **226**. The address range for the normal mode memory map may be defined by normal base and limit registers **216**. The normal mode memory map may map addresses to physical system memory that is not in CRC value area **252**, CRC protected data area **254**, or CRC error area **256**. However, other mapping schemes may also be used. For example, the normal mode memory map may map addresses to the CRC protected data

LSI DOCKET NO. 01-776

area. In this case, the data in a normal mode access may be protected, but a CRC will not be computed or compared for the transfer.

Physical system memory **250** may also include CRC value area **252** for storing CRC values and CRC error area **256** for storing CRC errors discovered by the CRC hardware engine.

5 The CRC value area address range is defined by CRC value base and limit registers **262**. The CRC error area address range is defined by CRC error base and limit registers **266**.

Turning to **Figure 3**, a block diagram illustrating data block area and CRC value area in system memory is shown in accordance with a preferred embodiment of the present invention. Data block area **310** includes data blocks 0-M. Each data block in the data block area has a
10 corresponding CRC value block in CRC value area **320** and an error information data block in CRC error area **330**.

Furthermore, each data block may be divided into sub blocks 0-N. Each data sub-block may have a corresponding CRC value sub-block in the CRC value area. Thus, when a transfer is not completed, the memory interface logic may restart with the next sub-block and the CRC hardware engine can continue generating or checking CRC values on a sub-block basis until the transfer is complete. In the eventuality that a transfer stops within a data sub-block, typically during a write transfer, the CRC hardware engine may store an intermediate value in system memory. In a preferred embodiment of the present invention, the intermediate value is stored in an unused portion of the CRC error area. When the transfer restarts, the CRC hardware engine
20 may retrieve the intermediate value from system memory and resume.

With reference now to **Figure 4**, a flowchart depicting the operation of memory interface logic is shown in accordance with a preferred embodiment of the present invention. The process begins and a system memory transfer start is detected (step **402**). A determination is made as to whether the memory transfer is within the generate base and limit range (step **404**). If the
25 transfer is a generate, a determination is made as to whether the transfer is a memory write (step **406**). If the transfer is a memory write, the process puts the address, a write indication, a generate indication, the port ID, and the data on the memory monitor bus (step **408**) and returns to step **402** to detect another system memory transfer. If the transaction is not a memory write in step **406**, the process returns to step **402** to detect another system memory transfer.

LSI DOCKET NO. 01-776

If the transfer is not a generate in step 404, a determination is made as to whether the memory transfer is within the check base and limit range (step 410). If the transaction is a check, a determination is made as to whether the transaction is a memory write (step 412). If the transfer is not a memory write, the process puts the address, a read indication, a check indication, the port ID, and the data on the memory monitor bus (step 414) and returns to step 402 to detect another system memory transfer.

If the transfer is a memory write in step 412, the process puts the address, a write indication, a check indication, the port ID, and the data on the memory monitor bus (step 416) and returns to step 402 to detect another system memory transfer. Returning to step 410, if the transaction is not a check, the process returns to step 402 to detect another system memory transfer.

Turning now to **Figure 5**, a flowchart illustrating the operation of a CRC hardware engine is depicted in accordance with a preferred embodiment of the present invention. The process begins and a transfer is detected on the memory monitor bus (step 502). Then, determination is made as to whether the transfer is a generate (step 504). If the transfer is a generate, the process computes the CRC value (step 506), stores the CRC value in the CRC value area of system memory (step 508), and returns to step 502 to detect another transfer.

If the transfer is not a generate in step 504, a determination is made as to whether the transfer is a check (step 510). If the transfer is not a check, the process returns to step 502 to detect another transfer. However, if the transfer is a check in step 510, a determination is made as to whether the CRC value is cached (step 512). If the CRC value is cached, the process retrieves the CRC value from the CRC value cache (step 514), and if the CRC value is not cached, the process retrieves the CRC value from the CRC value area in system memory (step 516) and stores the CRC value in the CRC value cache (step 517). Thereafter, the process calculates a CRC value (step 518) and compares the calculated CRC value to the retrieved CRC value (step 520).

Next, a determination is made as to whether an error is detected based on the comparison (step 522). If an error is detected, the process generates an error and stores the error in the CRC error area of system memory (step 524). Then, the process returns to step 502 to detect another

LSI DOCKET NO. 01-776

transfer. If an error is not detected in step 522, the process returns to step 502 to detect another transfer.

Thus, the present invention solves the disadvantages of the prior art by providing a dedicated hardware CRC computation engine to the memory interface integrated circuit to assure the integrity of data transferred between the system memory and storage devices. The CRC protection scheme of the present invention requires a small amount of initial software overhead to allocate the data, CRC value, and CRC error regions of the system memory. After the regions are allocated and the CRC generate and CRC check region registers are initialized, all CRC operations are transparent to the executing software. The calculations and optional checking occur "on-the-fly" simultaneously with the transfer of the data to or from the system memory. A small amount of additional memory bandwidth is required to perform the function. This allows for a much higher performance system than otherwise obtained if system processing resources were used to compute the CRC values and perform the checking.
